Testimony from Dr. Justin S. Mankin

Maine House Committee on Environment and Natural Resources
Consideration of LD 1870
Monday, May 5, 2025

Good morning. My name is Justin Mankin. I am a professor and climate scientist at Dartmouth, where I direct the Climate Modeling & Impacts Group[i]. My group and I work to understand the impacts of human-caused global warming on our water, food, recreation, infrastructure, and economic and physical security. Much of our scientific research centers on using publicly provided observations and openly available models to quantify the impacts and costs of global warming to date and to estimate how those may evolve into the future. Our goal is to improve our understanding of the consequences of warming for people and the things they value and to inform the difficult decisions those consequences will compel. My climate attribution work and that of my group has been published in leading peer-reviewed scientific journals, like *Science*, *Nature,* and the *Proceedings of the National Academy of Sciences*.[ii] I serve in a number of leadership and service roles in the climate science community, including with the National Climate Assessment, the National Academies, and the University Corporation for Atmospheric Research. I hold an undergraduate degree and a Masters of Public Administration from Columbia University, a Master of Science from the London School of Economics, and a PhD in climate science from Stanford University.

I am here to provide testimony on LD 1870 "An Act to Establish a Climate Superfund Cost Recovery Program to Impose Penalties on Climate Polluters." Briefly, I want to make the following four key points in my testimony and would be happy to field any questions the lawmakers have about each of these:

- **Firstly, using peer-reviewed, consensus scientific methods, scientists can *quantify* the economic losses a region like Maine has endured from the impacts of global warming to date.[iii]**

- **Secondly, using peer-reviewed, consensus scientific methods, scientists can *attribute* those losses back to particular emissions or emitters over a given time period, as considered by the legislation.[iv]**

- **Thirdly, using peer-reviewed, consensus scientific methods, scientists can estimate the net present value of future damages associated with *both* historical and future emissions.[v]**

- **Lastly, it is my opinion that we are systematically underestimating the economic costs of climate change to date, and that is because all of these climate damage cost accounting methods are inherently conservative or limited by data.**

For example, over the 1991-2022 period, we attribute that Maine's economy has lost over $6.5 billion from changes in extreme heat traceable back to all global greenhouse gas emissions over that same time. That is only one hazard, estimate over a 30 year period.

Losses from climate change abound. But who pays and how much? While these questions are ultimately being resolved in courts and in legislative bodies such as this, science can help provide answers to these questions. In particular, science can help by quantifying climate damages and attributing them to particular parties.

In general, there are three sets of costs to consider in assessing total damage due to climate change,[vi] and there are different methods to estimate each of these.

- The first is the cost of the damage promulgated by historical emissions. So these are the costs that have already manifested in Maine's economy owing to the hazards from the human-caused global warming to date.

- The second set of costs to consider are the costs that will arise from future hazards, which have their origins in historical emissions. The effects of carbon dioxide (CO_2) are cumulative, and CO_2 has a very long residence time in our atmosphere, such that some fraction of the first ton released at the dawn of the industrial revolution is still up there, warming our climate and generating impacts.[vii] This means that the emissions already released from fossil fuel combustion, and to which we can already attribute historical climate damages in a place like Maine, will continue to cause Maine damage into the future.

- The last cost to consider is the cost from future emissions. Decarbonizing our economy will take time and will itself be energy intensive; to the extent that it is reliant on fossil fuels, future emissions will generate future impacts, and those impacts, costs.

Thanks to the careful work of researchers like Rick Heede at the Carbon Majors database, we have the time varying Scope 1 and Scope 3 emissions data from major fossil fuel firms that position the apportioning of any one of the aforementioned costs back to these emitters.

There are a number of scientifically defensible and rational approaches to calculating the costs attributable to each of these terms and apportioning them to actors. I would generally classify the damage attribution work into two approaches. I emphasize that *both of these approaches have a rational basis*, which implies that the Treasurer would have options in how best to approach any accounting:

- The first approach relies on using some estimate of the marginal damage to Maine from a ton of emissions, like the social cost of carbon or SCC. The SCC is a dollar estimate of the discounted welfare costs associated with emitting one additional ton of carbon dioxide into the atmosphere. Right now, using various methodologies, the EPA places the SCC at $190 per ton[viii]. With that legally binding estimate in hand, one could apportion economic damages attributable to particular emitters or emissions based on a chosen covered period[ix].

- A second approach is one my research team, among others[x] has been working on, which we call an 'end-to-end' attribution. Our approach isolates and quantifies *particular* climate damages attributable to *particular* emitters and, owing to its modularity and flexibility, can be applied to myriad contexts (from single events to cumulative harms), emitters (from individual firms to nations), and climate change-driven hazards (from average

temperatures,[xi] to heat waves, to storms, droughts, floods, and others), given data availability. Our framework uses consensus, peer-reviewed methods and resolves nonlinearities in the relationships between greenhouse gas emissions, atmospheric concentrations, temperature changes, physical hazards, and damage. Our rigorous treatment of causation is designed to meet scientific and legal standards.

Climate attribution science is a well-established consensus science, informing synthesis reports like the Intergovernmental Panel on Climate Change[xii] and the National Climate Assessment[xiii], and has been used to establish causal links between global warming various climate hazards, like floods[xiv], droughts[xv], heat waves[xvi], snow loss[xvii], tropical cyclones[xviii], and other hazards. Similarly, there is considerable peer-reviewed, consensus work that documents and attributes the monetary losses from climate impacts—so called "climate damage assessments"[xix]. Damage assessments are often grounded in empirical or semi-empirical models called "damage functions" that connect climate-related extremes, like heat waves or floods, to policy-legible socioeconomic outcomes, like lives or income lost. With these damage estimates, decision-makers can then better understand the costs of climate inaction and weigh them against the net benefits of adaptation and mitigation.

These attribution methods rely on comparing outcomes in two groups, just like in a medical drug trial. In a drug trial, participants are randomly assigned into treatment and control groups. The individuals in the treatment group receive the drug, while those in the control group do not, and the medical outcomes among the two groups are compared. The power of randomizing who is in the treatment versus control groups allows us to show that even though individuals respond differently to the treatment, we can still make an attribution of the efficacy of the treatment.

We can extend this toy example to climate attribution in general. Our attribution methods rely on comparing outcomes in a world with versus without climate change. The distinction here is that we use models, rather than a randomized control trial, to construct the control group, or the counterfactual world without climate change. The power of this framework means we can remove a set of emissions associated with an emitter and evaluate how climate hazards and their associated damages would have looked differently. The difference between the work with versus without this emitter is the attribution of the causal role the considered emissions had on a state like Maine.

I am happy to delve into the mechanics of the approach if the Committee has questions. I also include our two scientific manuscripts with my testimony today, documenting our approach. Briefly, we use an integrated modeling framework built on consensus, peer-reviewed methods that allows us to build a transparent and reproducible chain of causality from emissions to damage, sampling the range of outcomes that are possible at each step. We do this by simulating from emissions to damage, leaving out a particular emitter, or set of emissions, creating a control group. We can then compare the two worlds, one as it is, and one without a particular set of emissions and compare the economic outcomes. That is our damage attribution.

We have applied this framework to assess the income lost due to historical emissions-driven changes in average temperature and heat waves. I note, however, that it can be extended to other hazards, like floods, or drought, and to other damages, like mortality or morbidity, depending on the use case, as the science rapidly develops.

What we know from these individual damage assessments is that the costs of climate change to date are far higher than previously understood. We have shown that for average temperatures, for extreme heat, and for climate variations that could be affected by climate change, like El Niño. Because the costs attributable to these individual hazards so far are so large, and they focus on quantities that are easily measured, it is my assessment that any accounting of the damages to date are an undercounting, and are therefore conservative.

Thank you for the opportunity to share our science with you today and I will standby for your questions.
